1 Introduction

The Network Time Protocol (NTP) is a protocol used to synchronize timekeeping among a set of distributed time servers and clients [1]. NTP has undergone significant evolution over the years since it was first proposed, culminating in the most recent NTP Version 3 described in RFC-1305. NTP is built on the Internet Protocol (IP) [2] and the User Datagram Protocol (UDP) [3], which provide a connectionless transport mechanism. It is specifically designed to maintain accuracy and robustness, even when used over typical Internet paths involving multiple gateways, highly dispersive delays, and unreliable nets.

The Simple Network Management Protocol (SNMP) is a management protocol widely used over the Internet for monitoring and control activities. SNMP also runs over UDP and IP. At a time when a wide variety of hardware and software components are becoming SNMP-capable, the lack of such capability in NTP prevents it from being integrated with other management applications. This report describes two SNMP MIBs developed for use with NTP that provide this sorely-needed management capability. The first is a regular MIB that allows any NTP server that implements this MIB to be managed by SNMP. The second is a Proxy MIB that allows access to all NTP servers regardless of whether or not they are SNMP-capable. The Proxy MIB permits the universal set of NTP servers all around the world to be available for SNMP access without any additional software deployment.

2 NTP System Architecture

The typical system architecture used by NTP consists of a number of primary reference sources, synchronized by wire or radio to national standards, and operated as primary time servers. Additional hosts or gateways run NTP with one or more of the primary servers and act as secondary time servers. The synchronization subnet is a connected network of primary and secondary time servers together with clients and interconnecting transmission paths. Under normal circumstances, it is intended that the synchronization subnet of primary and secondary servers assumes a hierarchical master-slave configuration with the primary servers at the root and secondary servers of decreasing accuracy at successive levels toward the leaves. The secondary servers distribute time via NTP to clients on the remaining local-net hosts.

An NTP client sends NTP messages to one or more servers and processes the replies received. Information included in the NTP message allows the client to determine the server time with respect to the local time and adjust the local clock accordingly. In addition, the message includes information to calculate the expected timekeeping accuracy and reliability, as well as select the best from possibly several servers.

An NTP association is formed between a client/server pair or between two peers when they exchange messages and one or both of them create and maintain an instantiation of the protocol machine. The association can operate in one of five modes: symmetric active, symmetric passive, client, server, and broadcast. The modes determine how and when the peers communicate with each other.

NTP Version 3 introduced an NTP Control Message format that can be used to perform NTP control and monitoring functions, such as setting the leap-indicator bits at the primary servers, adjusting the various system parameters and monitoring regular operations. Most

control functions involve sending a command and receiving a response, perhaps involving several fragments. Commands can read or write system variables, peer variables for a specified association, or variables associated with a radio clock or other device directly connected to a source of primary synchronization information.

3 The SNMP Network Management Framework

The SNMP Network Management Framework presently consists of three major components. They are:

- the SMI (Structure of Management Information), described in RFC 1902 [4], which specifies the mechanisms used for describing and naming objects for the purpose of management.
- the MIB-II, in RFC 1213 [5], which constitutes the core set of managed objects for the Internet suite of protocols.
- the protocol called SNMP, in RFC 1157 and/or RFC 1905 [6, 7], the protocol for accessing managed information.

In addition, Textual Conventions are defined in RFC 1903 [8], and conformance statements are defined in RFC 1904 [9].

Managed objects are accessed via a virtual information store, termed the Management Information Base or MIB. Objects in the MIB are defined using the subset of Abstract Syntax Notation One (ASN.1) defined in the SMI. In particular, each object type is named by an OBJECT IDENTIFIER, an administratively assigned name. The object type together with an object instance serves to uniquely identify a specific instantiation of the object. For human convenience, we often use a textual string, termed the descriptor, to refer to the object type.

The Framework permits new objects to be defined for the purpose of experimentation and evaluation.

4 A Framework for Managing NTP with SNMP

Until now NTP did not have an SNMP MIB defined for it, so the control and monitoring functions described in Section 2 could not be performed by traditional management protocols such as SNMP. As the standard management protocol for the Internet, SNMP has become widely implemented, deployed, and used for most routine management tasks. SNMP MIBs have been written and implemented for a wide variety of devices including routers, hubs, modems, network interfaces, hosts, printers, etc. NTP provides a service that is vital to the health of the Internet and therefore of crucial importance from the point of view of management. It is necessary that NTP be made SNMP-manageable so that this important gap can be filled.

This report describes two different approaches that we have developed for making NTP be SNMP-manageable. The first is a straightforward approach of designing and implementing an SNMP MIB for NTP. In this approach, an SNMP MIB is provided for each NTP server. The MIB is designed to contain all the management and control information available at this

server. Access to the MIB for management purposes is provided via an SNMP agent running at the same location as the NTP server. The SNMP agent communicates with the NTP server using NTP. To reduce the load imposed on the NTP server because of this communication, our implementation uses a caching mechanism to store some of the variables for short periods of time in the SNMP agent. Subsequent manager requests, if any, for these variables that are received within this time are satisfied using the cached values.

While the straightforward approach of having an SNMP MIB for each NTP server provides a long-term solution to the problem of managing NTP, it is not a viable short-term approach. There is a large existing infrastructure of thousands of NTP servers deployed worldwide on many different platforms in various administrative domains. It is unlikely that an SNMP MIB and agent will be implemented on many of these servers for the foreseeable future. As a result, the usefulness of the NTP MIB (and of the applications that use it) will be severely limited.

Our second approach overcomes this problem by providing a Proxy MIB for NTP. An SNMP agent that implements the NTP Proxy MIB establishes an NTP association with any NTP server, not just the local server. This server can be specified by the managing application by setting appropriate variables in the MIB. More than one server can be chosen for concurrent management. All communication between the SNMP agent and the NTP servers uses NTP. This scheme is thus not dependent on the availability of SNMP agents and MIBs on all NTP servers, yet the universal set of NTP servers becomes available to the SNMP community.

Because of the well-known security weaknesses of SNMP, no read-write access to NTP variables has been provided in the current designs of these MIBs. This is a particularly sensitive issue with the Proxy MIB because it potentially opens up all NTP servers worldwide to SNMP control creating a dangerous vulnerability to attack. As security issues are addressed and resolved in the SNMPv3 effort currently under way, the MIBs can be augmented with appropriate read-write variables.

5 The NTP MIB

The complete definition of the NTP MIB is provided in Appendix A. This MIB defines two new Textual Conventions and consists of three groups of variables.

The Textual Conventions are NTPTimeStamp and NTPLeapIndicator. NTPTimeStamp is an 8-byte string that represents an NTP timestamp as defined in RFC-1305. The DISPLAY-HINT clause allows the timestamp to be displayed as a 32-bit integer part followed by a decimal point and a 32-bit fractional part. NTPLeapIndicator is an enumerated integer used to code the two bits of the NTP Leap Indicator also defined in RFC-1305.

The ntpSystem group represents the System Variables of an NTP server. All of these are scalar variables.

The ntpPeers group represents the Peer Variables of an NTP server. These variables are maintained by the server for each NTP peer with which it currently has an association. The ntpPeers group contains only one table variable called ntpPeersVarTable. There is a separate row in this table for each peer. The table is indexed by the column ntpPeersAssocId which contains the association ID used by NTP to uniquely label each active association.

The third group in the NTP MIB is the ntpFilter group. Implementation of this group

is optional. It must be implemented when the filter and selection algorithms described in Section 4 of RFC-1305 are used. This group contains two tables ntpFilterPeersVarTable and ntpFilterRegisterTable. The first table, ntpFilterPeersVarTable, is an extension of the ntpPeersVarTable and provides an additional column called ntpFilterValidEntries that contains the number of valid entries in the ntpFilterRegisterTable for each peer.

The ntpFilterRegisterTable implements the Clock-Filter variables described in RFC-1305. These variables are maintained as a shift register for each peer with each stage of the shift register containing values associated with a single observation. As each new observation arrives, older values are shifted down in the register while the oldest value disappears. Each observation corresponds to a row in the ntpFilterRegisterTable and is indexed by ntpPeersAssocId and ntpFilterIndex.

6 The NTP Proxy MIB

The NTP Proxy MIB is completely specified in Appendix B. This MIB uses the two Textual Conventions defined in the NTP MIB and also defines an additional Textual Convention called NTPRowStatus. NTPRowStatus is similar to the RowStatus Textual Convention of RFC-1903 except that it only allows one create operation (the create-and-go of RowStatus) and does not allow row deletion. This is used in this MIB to create rows in the ntpProxyControlTable to ask the agent to start an association with a specified NTP server. As a result of this association, the agent then monitors the variables of the server and provides them in the various tables of this MIB. A management application is not allowed to delete the conceptual row; deletion is carried out by the agent in an autonomous manner when there is no management activity for the server for some period of time. The ntpProxyControlTable is indexed by the server's IP address.

The System variables are made available in the ntpProxyServerSystemTable which contains one row for each server being monitored. This table is also indexed by ntpProxyServerIPAddr.

The Peer variables are provided in the table ntpProxyPeersVarTable which is indexed by both ntpProxyServerIPAddr and ntpProxyPeersAssocId. This way there are multiple rows in this table for each server, with one row for each peer with which the server has an association.

The final table in this MIB is the ntpProxyFilterRegisterTable. This table is indexed by three variables, ntpProxyServerIPAddr, ntpProxyPeersAssocId, and ntpProxyFilterIndex. It has multiple rows for each server-peer combination, with each row holding one observation. The number of rows in this table used for each server-peer tuple is contained in the variable ntpProxyPeersFilterValidEntries which is a column of the ntpProxyPeersVarTable.

7 Implementation

This section is still under construction.

8 Conclusions

NTP is an important protocol for the Internet community as it regulates the clocks in myriads of hosts across the world. Until now, NTP has not been open to management and control with the Internet's standard management protocol, SNMP. This report contains a description of two proposed SNMP MIBs for managing NTP with SNMP. The first is a regular MIB for managing NTP servers, while the second is a proxy MIB. The proxy MIB provides the capability of managing any NTP servers even if those servers are not SNMP capable. We have implemented these MIBs in SNMP agents that will be shortly available for public access. These MIBs and agents form valuable tools for experimentation with management of NTP servers and using the data collected for a wide variety of interesting studies.

-- Textual Conventions:
--

NTPRowStatus ::= TEXTUAL-CONVENTION
     STATUS      current
     DESCRIPTION
             "The NTPRowStatus textual convention is modeled after the
             RowStatus textual convention of RFC 1903, but is simpler
             because it only allows one create operation (the create-
             and-go of RowStatus) and does not allow row deletion. If
             the state of the status column is 'notInService' and the
             management station tries to set it to 'create', the
             corresponding row is created and the operation is successful.
             If the set to 'create' is attempted when the status column
             is in state 'active', the operation fails and inconsistentValue
             is returned. A management station is not permitted to delete
             the conceptual row; deletion is carried out by the agent
             in an autonomous manner."
     SYNTAX      INTEGER {
                    -- the following values are states:
                    -- these values may be read, but not written
