1. Introduction

Sparse representation has achieved state-of-the-art results in many fields, such as image compression and denoising [1], face recognition [2,3], video-based action classification [4], etc. The success of this technique is partially due to its robustness to noise and missing data. For example, sparse representation-based classification (SRC) [2] yields impressive results in face recognition by encoding a query face image over the entire set of training template images and identifying the label of the query sample by evaluating which class yields the minimum reconstruction error. However, little effort has been made to apply this technique to classifying multi- variate time series (MTS) data.

Classifying multi- variate time series (MTS) is a challenging task in many areas, e.g., pattern recognition [5] and computer vision [6]. An MTS is an $m \times n$ matrix, where $m$ is the number of observations on an individual event captured by sensors such as video cameras, position trackers and cybergloves, while $n$ denotes the number of independent attributes [7], also known as variables [5,8] or features [9,10]. For each MTS, $m$ is typically varying due to different motion durations for each instance, while the number of attributes, $n$, is the same for all the series since they are recorded by the same set of devices. For conventional feature extraction methods, e.g., PCA and LDA, downsampling and interpolation are usually applied on each MTS in order to normalize the data length. However, downsampling may cause a loss of salient information [5], while interpolation may induce distortion to the original data [8].

Gesture MTS data possess both spatial and temporal information. While spatial information depicts the entire static pattern, temporal information contains the dynamic dependencies between adjacent recordings. Algorithms that exploit chronological order within time series, e.g., Dynamic Time Warping (DTW) [11,12] and Longest Common Subsequence (LCSS) [13], assume that similar signals must be recorded in the same order. However, motion order and direction may vary significantly among users presenting the same gesture. Consequently, such algorithms need to store all possible permutations of each gesture in memory and conduct pair-wise matching during recognition, resulting in excessive computation and storage requirements [14]. For example, a 2-stroke letter “t” requires $2! \times 2^2 = 8$ permutations to represent all possibilities, while an $l$-stroke gesture takes $l! \times 2^l$ permutations.

Notably, real-world gestures and movements, such as human gait and sign language, are performed according to a strict “grammar”. This observation indicates that effectively distinguishing complicated spatial patterns is the key to successful recognition, rather than exploiting temporal order [7,5,8]. Motivated by this observation and reasoning, we consider feature extraction for MTS data ignoring the temporal ordering. More specifically, we generalize the capability of SRC to classifying MTS data.

The performance of SRC relies on the quality of the dictionary. We propose a novel feature extraction technique, called Covariance Matrix Singular Value Decomposition for Kernelization (CovSVDK), which possesses three notable merits: CovSVDK is (1) invariant to inconsistent lengths and temporal disorder across MTS data;
(2) robust to the large variability within human gestures; (3) efficient to compute. In particular, the robustness of the feature extraction strategy is attributed to the fact that CovSVDK essentially enforces \( \ell_1 \) minimization algorithms to favor training samples that are consistently close to the query sample in every sub-feature space. Moreover, we propose a new approach to kernelize sparse representation. With this method, dictionary atoms are more separable for sparse coding algorithms and nonlinear relationships among data can be conveniently transformed into linear relations in kernel space, which leads to more effective classification. Finally, we evaluate the proposed framework over extensive datasets. For the Georgia-Tech HG database, a 100% recognition rate is stably achieved; over the High-quality Australian Sign Language (HAuslan) database, the recognition accuracy is greater than 91.2%; for the univariate UCR Time-Series Repository, the proposed classifier outperforms competing methods by achieving the lowest error rate on 10 out of 20 datasets.

The remainder of the paper is organized as follows. First, we give a brief review of related work and establish the problem formulation in Section 2. In Section 3, the proposed method is presented. Experiments and comparison with existing methods are presented in Sections 4 and 5. Finally, we summarize in Section 6 and note future directions.

2. Related work and problem formulation

2.1. Related work

Many algorithms have been proposed to measure the similarity among multi-dimensional time series, e.g. Hidden Markov models (HMMs) [15], DTW [11,12], LCSS [13], and Mixture of Bayes Network Classifier [9], among others. Principal components (PCs) based methods are, perhaps, the most widely known similarity measure for multi-attribute time series, with the approach first defined by Krzanowski [16] in 1979. Many subsequent PC efforts focused on computing the similarity value using different weighting strategies to aggregate the inner products between PC pairs [5,7,8].

For instance, Li et al. proposed a similarity measure for motion streams using only the largest singular value and the corresponding singular vector [7]. In [6], the authors further proposed k Weighted Angular Similarity (KWAS) by considering the k largest singular value/vector pairs. Yang and Shahabi [5] proposed a similarity measure, called Extended Frobenius norm (Eros), which included all the singular values by employing a heuristic aggregating function to compute universal weights for all MTS data. The similarity measure is a weighted sum of inner products between each pair of singular vectors. In practice, however, variance is highly concentrated in the several largest eigenvalues and the small values are typically considered as redundancy or noise. Hence, Eros is vulnerable to noise. Yang and Shahabi further extended their approach by using Eros for Kernel PCA, termed KEros [8].

Recently, some researchers reported the limitation of SRC [2] in classifying nonlinear data. Zhang et al. [17] proposed the kernel sparse representation-based classifier (KSRB) by introducing the kernel trick. However, their approach relies on kernel-based dimensionality reduction techniques and thus does not offer a direct generalization to sparse representation in kernel space. Gao et al. [18] proposed kernel sparse representation (KSR). However, the KSR objective function cannot be solved by standard sparse coding algorithms as it requires solving a quadratic programming (QP) problem, which is of higher computational complexity than \( \ell_1 \) minimization.

2.2. Problem formulation

In a \( k \)-label MTS data classification problem, we define the training set as \( T = \{ T_i \}_{i=1}^N \), where \( T_i = \{ t_{ij} \}_{j=1}^{n_i} \) is a subset for the \( i \)-th class with \( n_i \) samples, and define the query sample as \( x \). Also, denote \( N = \sum_{i=1}^N n_i \) as the total number of training samples.

There is significant current interest in using SRC [2] to classify audio, image and video signals. It is therefore desirable to explore its capability in the field of MTS data classification. To achieve this goal, several important issues must be addressed: (1) An effective feature extraction method is needed to process large-scale MTS datasets. The method should be efficient in computation and memory consumption, and invariant to inconsistent lengths and temporal disorder across MTS samples. (2) A general formulation of sparse representation suitable for various pattern recognition tasks is also desired. SRC assumes that training atoms reside on a linear manifold and are distinguishable by \( \ell_1 \) minimization algorithms. While this premise holds for face images, it does not necessarily hold for other types of data.

3. Proposed method

This section details methods for effectively extracting MTS data features and presents a novel approach to kernelizing sparse representation for classification.

3.1. Feature extraction for MTS data

3.1.1. SVD properties of MTS data

For an \( m \times n \) MTS matrix \( \Xi \), \( m \) observations and \( n \) attributes, \( m \) is typically much larger than \( n \) and varies across different samples. In order to avoid performing SVD on \( m \)-varying \( \Xi \), we treat each attribute (columns in the \( \Xi \)) as a random variable and compute the covariance matrix of \( \Xi \) as

\[
\Sigma = \Xi^T \Xi
\]

where \( \Xi^T \) denotes the mathematical expectation and \( \Sigma \) is of fixed dimension \( n \times n \) (here \( n \gg 2 \)). By calculating the \( \Sigma \) of \( \Xi \), we discard the ordering information and thus overcome the problem of temporal disorder across MTS samples, since each entry in \( \Sigma \) is an inner product between two columns in \( \Xi \) that is invariant to the row-switching of \( \Xi \).

Applying SVD to the covariance matrix yields \( \Sigma = U \Lambda U^T \), where \( U = [u_1, \ldots, u_n] \) is a singular vector matrix with orthonormal columns and \( \Lambda = \text{diag}(\rho) \) with \( \rho = [\lambda_1, \ldots, \lambda_n] \) being a vector with singular values descendingly sorted. \( \text{diag} \) is the operator that transforms \( \rho \) into a diagonal matrix by putting entries of \( \rho \) along the main diagonal in the matrix. Similarly, the covariance matrix of MTS \( \Xi \) can be expressed as \( \Sigma = \Xi \Xi^T \), where \( \Xi = [\xi_1, \ldots, \xi_n] \) and \( \Xi^T = \text{diag}(\eta) \) with \( \eta = [\eta_1, \ldots, \eta_n] \). Since \( \Sigma \) is positive semi-definite, its SVD is equivalent to eigenvalue decomposition.

If two MTS \( \Xi \) and \( \Xi' \) are similar to each other, \( \| \Xi - \Xi' \|_2 \) should be close to zero. In other words, the singular vector \( u_i \) of \( \Sigma \) should resemble \( v_i \) of \( \Sigma' \) in direction and the singular value \( \lambda_i \) of \( \Sigma \) should also be close to \( \eta_i \) of \( \Sigma' \). Further discussions on the SVD properties of MTS can be found in Appendix A.

3.1.2. Simple features for sparse representation

For simplicity, we indicate the \( i \)-th training sample as \( \xi_i \). Applying SVD to the covariance matrix, we get \( \Sigma = U \Lambda U^T \), where \( U = [u_1, \ldots, u_n] \) and \( \Lambda = \text{diag}(\rho) \) with \( \rho = [\rho_1, \ldots, \rho_n] \). Note that \( u_i \in \mathbb{R}^m \) and \( \rho_i \) stand for the \( j \)-th singular vector (principle component) and the \( j \)-th singular value of \( \Xi \), respectively. We denote \( \Xi' = [u_1', u_2', \ldots, u_n'] \in \mathbb{R}^{m \times N} \) as the dictionary containing the \( j \)-th singular vectors extracted from all \( \xi_i \), with \( \| u_i' \|_2 = 1 \) for \( i = 1, \ldots, N \). Given a query sample \( x \) and corresponding \( \Sigma = \Xi \Xi^T \), denote the \( j \)-th singular vector of \( x \) as \( v_j \) and let \( \eta = [\eta_1, \ldots, \eta_n] \) be the
vector containing all the singular values in Ω sorted in the descending order. A simple strategy for classifying x is to treat a particular ω as the feature of x and employ SRC [2] to identify the feature by solving

\[
\omega^d = \arg\min_{\omega^d} ||\omega^d|| \text{  subject to } B^T \omega^d = \nu^d.
\]  

(2)

Obtaining \( \omega^d \in \mathbb{R}^N \), x can be classified by evaluating the class-wise reconstruction error based on B^d.

The above strategy using one singular vector (e.g. the top one) may work properly with well-separated data. However, real-world gesture recordings are always vulnerable to noise or large variability among individuals. Therefore it is desirable to take into account several most important singular vectors to improve the robustness of the algorithm. In addition, the discriminative information within the singular values should also be exploited.

3.1.3. Robust features for sparse representation

Consider a robust feature vector constructed by unifying the top s singular values and the associated singular vectors (ssn). Suppose that we have obtained \( \omega^d \) by solving Eq. (2), for all \( j = 1, \ldots, s \). Without violating the equality in the constraint of Eq. (2), we can equivalently rewrite \( B^T \omega^d = \nu^d \) as

\[
B^d \omega^d = \begin{bmatrix} \frac{x_1^s}{||x_1||_2} - u_1^s \frac{x_2^s}{||x_2||_2} - u_2^s \ldots \frac{x_n^s}{||x_n||_2} - u_n^s \end{bmatrix} \omega^d = \frac{\omega^d}{||\omega^d||} \nu^d
\]  

(3)

where \( \omega^d = \Delta \omega^d \) with \( \Delta = \text{diag}(\text{diag}(||x_1||_2^2/||x_2||^2_2, \ldots, ||x_n||_2^2/||x_n||^2_2)) \).

Applying the same procedure to each pair of \( B^d \) and \( \nu^d \) for all \( j = 1, \ldots, s \), we get

\[
\begin{align*}
B^1 \omega^1 &= \frac{\omega^1}{||\omega^1||_2} \nu^1, \\
B^2 \omega^2 &= \frac{\omega^2}{||\omega^2||_2} \nu^2, \\
&\ldots \\
B^s \omega^s &= \frac{\omega^s}{||\omega^s||_2} \nu^s.
\end{align*}
\]  

(4)

Ideally, if x is sufficiently similar to \( t_i \), \( \nu^i \) should resemble \( u^i \), so should \( \omega^i \) and \( \Delta \) for all \( j = 1, \ldots, s \). Therefore, in reconstructing each \( \nu^i \), the \( u^i \) should be coded with large coefficient. In other words, if each \( u^i \) of \( t_i \) contains most in representing \( \nu^i \) of x, then \( t_i \) should be similar to x. Then, the class to which \( t_i \) belongs should yield the minimum error in reconstructing x, which indicates that x is of the same label as \( t_i \).

Motivated by this intuition, we enforce each \( \nu^i \) of x to be represented via a universal sparse code \( \alpha \) over the corresponding \( B^i \). By substituting \( \omega^d \) with \( \alpha \) for all \( j = 1, \ldots, s \), Eq. (4) can thus be simplified as

\[
\begin{bmatrix} B^1 \nu^1 & B^2 \nu^2 & \ldots & B^s \nu^s \end{bmatrix}^T \alpha = \begin{bmatrix} \frac{\omega^1}{||\omega^1||_2} \nu^1 & \frac{\omega^2}{||\omega^2||_2} \nu^2 & \ldots & \frac{\omega^s}{||\omega^s||_2} \nu^s \end{bmatrix}^T.
\]  

(5)

where \( [B^1 \nu^1, B^2 \nu^2, \ldots, B^s \nu^s]^T \) is a vertical concatenation of all the submatrices \( B^i \) and the right hand side is a super-vector by concatenating all \( \nu^i \). Thus the classification scheme based on unifying the top s pairs of singular values/vectors can be formulated as

\[
\alpha = \arg\min_{\alpha} ||\alpha||_1 \text{ subject to Eq. (5)},
\]  

(6)

where columns in \( [B^1 \nu^1, B^2 \nu^2, \ldots, B^s \nu^s]^T \) are normalized to unit \( \ell_2 \)-norm.

Definition 1 (CovSVDK). Given an MTS t, its covariance matrix is decomposed as \( \Sigma = U \Lambda U^T \) by SVD, where \( U = [u_1, \ldots, u_s] \) is a singular vector matrix with orthonormal columns and \( \Lambda = \text{diag}(\rho) \) with \( \rho = [\lambda_1, \ldots, \lambda_n] \) is a diagonal matrix with singular values descendingly sorted on the main diagonal. The CovSVDK feature for t is defined as

\[
\phi(t) = \frac{\lambda_1}{||\rho||_2} u_1^T, \frac{\lambda_2}{||\rho||_2} u_2^T, \ldots, \frac{\lambda_s}{||\rho||_2} u_s^T \in \mathbb{R}^m,
\]  

(7)

where s subject to

\[
s = \arg\min_{s} \left\{ \sum_{i=1}^{s} \frac{1}{\lambda_i} \geq \epsilon \right\}
\]  

(8)

for a pre-selected energy threshold, \( \epsilon \).

In practice, it is common to empirically set a universal s for all MTS data such that most energy is preserved within the top s singular values. The name CovSVDK stands for Covariance Matrix SVD for Kernelization.

Definition 2. Given s, define \( \Phi \) as a collection of features extracted from the training set T according to Definition 1, and write \( \Phi = \{\phi(t_{1,1}), \ldots, \phi(t_{1,n}), \ldots, \phi(t_{s,n})\} \in \mathbb{R}^{m \times N} \).

Furthermore, define \( y = \Phi(x) \) as the feature of the query sample x.

3.2. Kernelizing sparse representation for classification

The discrimination capability of SRC relies on the quality of the dictionary. In other words, the atoms associated to different classes must be distinguishable or separable from the perspective of \( \ell_1 \) minimization algorithms. In some real-world applications, however, computing the sparse representation over a dictionary of original training features can yield undesirable classification results. One such example is the Iris dataset (from UCI machine learning archive). As is commonly used for analyzing the performance of various classifiers, two features for each sample, regarding pedal length and pedal width, are extracted and formed into a 2D feature vector, as shown in Fig. 1(a). The three classes (points in red, green and blue) are distributed closely along the same radius direction. Obviously, the extracted 2D feature vectors are sufficiently discriminative for traditional classifiers, e.g., k-Nearest-Neighbors (kNN) and Support Vector Machines (SVMs). On the other hand, SRC normalizes training samples with unit \( \ell_2 \)-norm and employs the normalized training samples as dictionary atoms.\(^1\) As shown in Fig. 1(b), the atoms are located on the unit circle with severe overlapping in the middle of the point scatter. The atoms within the overlapping region are inseparable and

\(^1\) Normalization is typically performed to avoid trivial solution and is reasonable in face recognition, since images of a subject under different intensity levels are still considered to be same-class. In other words, the magnitudes of feature vectors are not considered as discriminative information in face recognition.
consequently cause $\ell_1$ minimization algorithms the confusion in selecting the true atoms. Thus, SRC neglects the magnitude information and suffers the drawback of losing its discrimination capability in classifying data that are distributed along the same radius direction [17,19].

We propose the kernelized sparse representation to overcome this shortcoming of SRC. This is possible by kernelizing sparse representation, the classification strategy of SRC can be applied to general pattern recognition tasks including MTS gesture recognition, time series classification, etc.

Kernel trick is a widely applied technique in machine learning that can adapt linear algorithms to nonlinear cases, by mapping training features $\phi(\cdot)$ from the original space $\mathcal{X}$ into some kernel space $\mathcal{F}$, in which the new kernel features $\psi(\cdot)$ are more separable for a certain type of classifiers and the nonlinear relationships among $\phi(\cdot)\in\mathcal{X}$ can be transformed into linear ones among $\psi(\cdot)\in\mathcal{F}$.

Let $\Psi = [\psi(t_1),\ldots,\psi(t_1),\ldots,\psi(t_m),\ldots,\psi(t_{m^2})]$ be the collection of training kernel features in $\mathcal{F}$. Given a test sample $x$, we want to solve the sparse representation $\alpha$ of $\psi(x)$ over $\Psi$. However, this is typically infeasible, as (1) usually the mapping $\psi$ is implicit, meaning that direct evaluation of the fitness term $\psi(x) = \Psi\alpha$ is impossible [17]; (2) $\mathcal{F}$ may be of infinite dimension, causing that the computational complexity is intractable; (3) even though we know the mapping implicitly, $\psi^T\Psi$ may not be invertible, resulting that the left inverse does not exist and thus no explicit solution to $\psi(x) = \Psi\alpha$ is available. To overcome these difficulties, we introduce a relaxation to the fitness constraint term as

$$
\left\| \begin{bmatrix} \psi(x) \\ 0 \end{bmatrix} - \begin{bmatrix} \Psi \\ \Omega \end{bmatrix} \alpha \right\|_2 \leq \varepsilon
$$

(11)

where $\Omega\in\mathbb{R}^{N\times N}$ is a zero vector, $I\in\mathbb{R}^{N\times N}$ is the identity matrix, $\varepsilon$ is an arbitrarily small positive constant representing the error tolerance, $\gamma$ is a small positive constant. Satisfying Eq. (11) is equivalent to minimizing the ridge regression problem $L(\alpha) = \|\psi(x) - \Psi\alpha\|_2^2 + \gamma \alpha^T\alpha$.

Setting the gradient of $L(\alpha)$ with respect to $\alpha$ equal to zero, the solution space of $\alpha$ is obtained as

$$
\Psi^T\psi(x) = (\Psi^T\Psi + \gamma I)\alpha
$$

(12)

where $\Psi^T\psi(x)$ is an $N \times 1$ vector and $\Psi^T\Psi$ is an $N \times N$ positive semi-definite matrix. Regularized by $\gamma$, $(\Psi^T\Psi + \gamma I)$ is invertible, yielding that $\alpha$ is the global minimizer to $L(\alpha)$. In other words, enabling Eq. (12) is equivalent to satisfying Eq. (11). Thus, we can employ Eq. (12) as the fitness constraint in sparse coding.\(^2\)

To improve the efficiency in $\ell_1$ minimization and to ensure the solution to be sparse, a random matrix $\Phi\in\mathbb{R}^{d\times N}$ obeying Gaussian or Bernoulli distribution (we use Gaussian here) is often employed to project vector $\Psi^T\psi(x)$ and columns in $(\Psi^T\Psi + \gamma I)$ into some $d$-dimensional random subspace, where $d\ll N$.

Define the $K = \Psi^T\Psi$ as a Gram matrix, with elements $K_{ij} = k(\phi(t_i), \phi(t_j))$, where $k(\cdot, \cdot)$ is a valid kernel function. By denoting $\mathbf{y} = \Psi^T\psi(x) = k(\cdot, x)\in\mathbb{R}^N$ and substituting $K$ for $\Psi^T\Psi$ in the new fitness constraint Eq. (12), the kernelized sparse representation under random projection $\Phi$ is formulated as

$$
\alpha = \arg\min_{\alpha} \|\alpha\|_1 \quad \text{subject to} \quad \Phi(K + \gamma I)\alpha = \Phi\mathbf{y}.
$$

(13)

From Eq. (13), we can see that the linear relationship between kernel features $\psi(x)$ and columns in $\Psi$ has been depicted entirely in terms of the linear combination between the kernel function values in vector $\mathbf{y}$ and the corresponding ones in matrix $K$. For the purpose of effectively classifying MTS gestures and time series data, we further propose two kernel functions based on the CoSVD features.

**Proposition 1** (Kernel function). Let $t$ and $p$ be two samples and let $\phi(t)$ and $\phi(p)$ be their extracted feature vectors. The proposed kernel function is defined as

$$
k_k(\phi(t), \phi(p)) = \exp[k_1(\phi(t), \phi(p))] = \psi(t)^T\psi(p)
$$

(14)

where $\psi(\cdot)\in\mathcal{F}$ and $\phi(\psi)\in\mathcal{F}$ are kernel features for $t$ and $p$, via some implicit nonlinear mapping $\psi$. In particular, for MTS data, $\phi(t)$ and $\phi(p)$ are extracted according to Definition 1 and the kernel function $k_k(\cdot, \cdot)$ can be written as

$$
k_k(\phi(t), \phi(p)) = \psi(t)^T\psi(p) = \sum_{i=1}^N \left( \frac{\lambda_i a_i}{\|p\|_2 \|q\|_2} \right) u_i^T v_i.
$$

(15)

Note that kernel features $\psi(\cdot)\in\mathcal{F}$ are of infinite dimension. By working directly on the kernel function however, we can implicitly exploit the kernel space of high, or even infinite dimension, without the need of knowing mapping $\psi$. By using the proposed kernel function $k_k(\cdot, \cdot)$, the atoms embedded in a 2D random subspace for the Iris dataset are separable for $\ell_1$ minimization algorithms, as shown in Fig. 1(c).

By incorporating the classification rule of SRC into Eq. (13), we obtain the newly proposed classifier, called Kernelized SRC, which shall be discussed in the following two sections.

3.3. Training

Building a discriminative dictionary is critical to the effectiveness of sparse representation based classifiers. Given a training
set $T$, we now describe how to construct such a dictionary via kernel trick based on specific feature extraction methods. To elaborate, we first use median filter to preprocess each sample (in the noisy case). Then we loop through all training samples to compute the features. For MTS data, the CovSVDK feature is extracted individually from each training sample. For the case of univariate time series data, we simply employ each raw time series as a feature vector, since CovSVDK is effective only when $n \geq 2$. Next, we construct a dictionary as the localized kernel matrix $K + \gamma I$. Finally, we may employ a random matrix $P$ to improve the efficiency in classification. The whole training process is summarized in Algorithm 1.

Algorithm 1. Kernelized SRC: Training.

Require:  
1. Preprocess each training sample with median filter (optional)
2. for $i = 1$ to $k$ do  
3. for $j = 1$ to $n_i$ do  
4. Feature extraction for each $t_{ij} \rightarrow \phi(t_{ij})$ (for MTS data, $\phi(t_{ij})$ is extracted according to Definition 1)  
5. end for  
6. end for  
7. Compute $K$ according to Proposition 1  
8. Construct dictionary as $K + \gamma I$  
9. Secure sparsity in the solution vector by employing $P$ for dimensionality reduction (optional)  
10. return $P$ and $P(K + \gamma I)$

3.4. Classification

In this section, we discuss how to classify a query sample using the proposed Kernelized SRC. Having $x$ as a test sample, we first preprocess it with the same technique as in training and extract its feature as $y = \phi(x)$. Then based on the kernel function defined in Proposition 1, we have $y = k(\cdot, x) = [k(\phi(t_1), \phi(x)), \ldots, k(\phi(t_n), \phi(x))] \in \mathbb{R}^n$. Next, random projection can be performed to reduce dimensionality. Then, we find the sparse representation $\alpha$ of $y$ over $P(K + \gamma I)$ by solving the optimization problem Eq. (13), which is called Basis Pursuit Denoising (BPD) [20]. Notice that the sparse coefficients, $\alpha$, can be computed by other fast iterative algorithms, such as Orthogonal Matching Pursuit [21] or Compressive Sampling Matching Pursuit [22]. Experimental results reported in the following sections are based on the $\ell_1$ Magic implementation of BPD [23]. Finally, we identify $x$ as class $i$ based on the decision rule as

$$ i = \arg \min_{i \in [1 \ldots 3]} \|Py - P(K + \gamma I)\delta_i(\alpha)\|_2, $$

where $\delta_i(\alpha) = [0, \ldots, a_{i1}, \ldots, a_{in}, \ldots, 0]$. To cope with unbalanced classes, an alternative decision rule $i = \arg \min_{i \in [1 \ldots 3]} \|Py - P(K + \gamma I)\delta_i(\alpha)\|_2 / \|\delta_i(\alpha)\|_1$ can be employed. The classification procedure is summarized in Algorithm 2.

Algorithm 2. Kernelized SRC: Classification.

Require: Test sample $x$, random matrix $P$ and dictionary $P(K + \gamma I)$
1: Preprocess test sample with median filter (optional)
2: Feature extraction for $x \rightarrow y = \phi(x)$ according to Definition 1
3: Based on the kernel function defined in Proposition 1, compute $y = k(\cdot, x) = [k(\phi(t_1), \phi(x)), \ldots, k(\phi(t_n), \phi(x))] \in \mathbb{R}^n$
4: Random subspace embedding via $P$ (optional)
5: Find the sparse coefficient vector $\alpha$ by solving Eq. (13)
6: $i = \arg \min_{i \in [1 \ldots 3]} \|Py - P(K + \gamma I)\delta_i(\alpha)\|_2$
7: return $i$

4. Experiments on classifying real-world MTS data

In this section, we conduct experiments to demonstrate the promising performance of the proposed framework, i.e., CovSVDK + Kernelized SRC, over three online public-access databases, i.e., the Georgian-Tech Human Gait (Georgia-Tech HG) database, Australian Sign Language (Auslan) database and High-quality Australian Sign Language (HAuslan) database. The Georgia-Tech HG database was obtained via 12 video cameras; the Auslan was generated by Powergloves; and the HAuslan was generated by two 5DT gloves and two position trackers. To verify the effectiveness of the proposed CovSVDK feature, we use the linear kernel $k_{\gamma}(\cdot, \cdot)$ for all experiments in this section. Feature vector $\phi(\cdot)$ for each MTS is extracted according to Definition 1. For each particular database, the parameter $\gamma$ is manually selected and is consistent for all MTS
data within the database. As in [2], atoms in \( P(K + \lambda) \) are normalized to unit \( \ell_2 \)-norm prior to \( \ell_1 \) minimization. \( \gamma \) is set to 0.001.

We evaluate and compare the proposed CovSVDK, with Principle Component Analysis (PCA) and Linear Discriminant Analysis (LDA). For PCA and LDA, all MTS data are interpolated or downsampled to the average length, in each database. We compare the proposed classifier Kernelized SRC with two popular classifiers, i.e., K-Nearest Neighbor (KNN) with \( k=3 \), Support Vector Machines (SVM) and with the coding strategy by computing the least square solution to Eq. (12), termed LS. For Kernelized SRC and LS, the decision rule is Eq. (16). For KNN and SVM, columns in \( \Phi \) are employed as training data and \( \phi(x) \) is used as the test sample. The SVM toolbox can be found at [24]. As shown in the following, our method consistently achieves high performance over these databases.

4.1. Georgia-Tech HG database

The Georgia-Tech HG database, used for human identification from a distance, is a collection of human gaits from 15 subjects. Samples of subjects were captured by cameras at 4 different controlled speeds [9]. Every subject was required to walk 9 times at every controlled speed and finally, 36 samples were obtained for every subject. A sample is a time series of gaits with varying length. By means of 22 markers on the subject, a gait is defined by 66 attributes (variables), i.e., the 3-D coordinates of those markers [25,26]. The evaluation uses all the 540 samples in the database.

Among the 36 samples per subject, 30 samples are randomly collected into the training set while the remaining 6 samples are used for testing.

By transforming the kernel matrix into a low dimensional random subspace, we can reduce the computation cost of \( \ell_1 \) minimization. In order to evaluate the effectiveness of random projection, we randomly select parts of the overall 22 markers and set the parameter \( s=5 \) uniformly, such that 5 singular value/vector pairs are extracted by CovSVDK for each MTS. Fig. 2(a) indicates that the proposed approach can achieve 100% recognition rate when a random subspace is of only 20 dimensions and only 11 markers are utilized. Hence, in the following experiments over this database, kernel matrices are projected onto a random subspace with dimension 20 to improve computation efficiency.

Remark. It is worthy to point out that, for \( \ell_1 \) minimizers, the dimensionality reduction induced by random projection is not a requisite. The purpose of embedding the dictionary atoms into some low-dimensional subspace is two-fold: (1) speed-up \( \ell_1 \) minimization; (2) enforce the dictionary to be overcomplete such that the solution tends to be sparse. The first concern is desired from a practical efficiency perspective while the second concern is preferred by the decision rule (Eq.(16)) so as to secure satisfactory recognition rate. We can see from Fig. 2(b) that the recognition rate increases as the dimension of the random subspace becomes higher. For completeness, we also evaluate the proposed approach over the Georgia-Tech HG database without performing dimensionality reduction. Fig. 2(a) illustrates that the accuracy obtained without dimensionality reduction is similar to those with dimensionality reduction.

To evaluate the proposed framework in a more challenging scenario, we downsample the raw gesture data into 1/5 of its original length and utilize only part of the overall 66 attributes. As shown in Fig. 3, our method robustly achieves 98.9% recognition, leading SVM by approximately 10% in accuracy.

As shown in Fig. 4, at 9, 4, and 1 dimension(s) of the feature subspace respectively, PCA, LDA and CovSVDK achieve 100% recognition rate. Therefore, compared with PCA and LDA, the proposed CovSVDK is more effective in preserving discriminative information for classification. Finally, Table 1 shows that in classifying MTS data, the proposed linear kernel function \( k(\cdot,\cdot) \) significantly outperforms three other popular kernel functions, i.e., exponential, polynomial and Gaussian kernel functions.

4.2. Australian sign language (Auslan) database

Contributed by 5 individual signers, the Auslan database contains 95 one-hand signs. 70 samples were collected for each sign and a sample is comprised of varying-length time series for a
Using the same CovSVDK features, we applied to evaluate spatial trajectory recognition algorithms. In the first experiment over the Auslan database, we consider a binary classification task. With the same experiment setup as [9], we form a subset by using 10 signs and choose, from the 15 attributes, 8 attributes, namely the x, y and z coordinates of the palm, the roll angle of the palm, the bend values of the 5 fingers and 4 additional setting values. Over this database, we conduct comparative study by evaluating the proposed approach (CovSVDK + Kernelized SRC) against several state-of-the-art algorithms, i.e., discriminative mixture learning (MixCML [9]), Dynamic Time Warping (DTW) [11], Fourier Descriptors [27] and SRC [2]. Recognition rates are cited from literature for the first three methods. Results for SRC are reported based on our own implementation.

The HAuslan database consists of 95 two-hand signs. Compared with the Auslan database, the number of samples per sign is reduced to 27 and the number of attributes is increased to 22, (11 attributes for each hand). The 11 attributes for one hand are the same as those in Auslan database excluding the 4 setting values.

First, to illustrate the capability of our method in classifying large-scale datasets, all 95 sign classes are used. Since the HAuslan database contains much more classes but fewer samples per class than previous two databases, 24 randomly selected samples are assigned to training set for each sign, while the remaining 3 samples are collected into the test set. Note that the kernel matrix contributed by all training samples is of size $2280 \times 2280$, to which performing $l_1$ minimization is computationally expensive. For efficient classification, we employ random projection to reduce the row dimension of the kernel matrix to 40, which is just 1.8% of its original size. In addition, considering that the subtle differences among some signs, we set $c = 99.9\%$ so as to involve sufficient gesture details to enable effective classification. To improve robustness and remove outlier atoms from the dictionary, we apply a refinement process to the dictionary by only preserving the atoms with large reconstruction coefficients, based on the solution to Eq. (13). Then, the newly formed sub-dictionary is fed to the classifier. The recognition rates of the proposed framework (CovSVDK + Kernelized SRC) are presented in Table 5 and in Fig. 7.

Next, we compare CovSVDK + Kernelized SRC with various combinations of feature extraction strategies and classifiers. For CovSVDK, we set the parameter $s_{max} = 6$ and for PCA, we set the energy preservation ratio $c_{max} = 99.9\%$, which results in a maximal 30 features. The maximal number of linear features for LDA is 21. Fig. 8 shows that although Kernelized SRC using PCA and LDA features yields inferior performance to SVM, when working jointly with CovSVDK, Kernelized SRC outperforms other combinations of features and classifiers. This result confirms the effectiveness of the proposed framework. The highest recognition rates and the corresponding dimensions of feature space for various methods are summarized in Table 6. As shown in Table 7, in classifying MTS data, the proposed kernel function $k_{L} (\cdot , \cdot)$ again significantly outperforms three other widely used kernel functions, i.e., exponential, polynomial and Gaussian kernel functions.

Finally, a comparison among state-of-the-art methods in the 25-label classification problem is given in Table 8, which further validates the superiority of the proposed method.

4.3. High-quality Australian sign language (HAuslan) database

The HAuslan database consists of 95 two-hand signs. Compared with the Auslan database, the number of samples per sign is reduced to 27 and the number of attributes is increased to 22, (11 attributes for each hand). The 11 attributes for one hand are the same as those in Auslan database excluding the 4 setting values.

In literature, we notice that this database has been widely used to evaluate spatial trajectory recognition algorithms. In the second experiment, for fair comparison, we only keep 3 attributes, i.e., $x$, $y$ and $z$ coordinates. Fig. 5 gives some examples for 8 signs. Using the same CovSVDK features, we first compare two classifiers, i.e., Kernelized SRC and SRC based on 10-fold cross-validation. Then keeping the experiment setup consistent as in [27], the proposed approach (CovSVDK + Kernelized SRC) is compared with DTW [11] and Fourier Descriptor [27] based on 2-fold cross-validation. Classification results for aforementioned methods are summarized in Table 4, which indicates that the proposed algorithm is competitive among these advanced trajectory recognition algorithms.

The effectiveness of Kernelized SRC is illustrated in Fig. 6, in which, for better visualization, 15 samples per sign are utilized for training while the remaining 5 samples are for testing. The 2/3D manifolds are obtained by projecting the dictionaries (with and without the kernel trick) into random subspace. Clearly, with kernel trick, samples from different classes are more separable than those without the kernel trick, which reveals that the proposed classifier is more robust than SRC [2] when dealing with cluttered data.

---

5 This is due to the fact that Kernelized SRC uses the simplest linear kernel while SVM employs the more advanced RBF kernel.
4.4. Evaluating the robustness

In this section, we evaluate the robustness of the proposed framework by employing the Sparsity Concentration Index (SCI) [2] to detect outliers. The SCI is defined as

\[
SCI(\alpha) = \frac{k \cdot \max_i \| \delta_i(\alpha) \|_1/\| \alpha \|_1 - 1}{k-1}.
\]  

(17)
where \(\alpha\) is the solution to Eq. (13) and \(\delta(\alpha)\) is the characteristic function defined in Eq. (16). If a test sample can be entirely expressed by the training samples from only a single class, then \(SCI(\alpha) = 1\); while, in the other extreme, if the coefficients in \(\alpha\) spread evenly over the classes, then \(SCI(\alpha) = 0\). The intuition lies in the fact that, for a test sample belonging to a certain class in the training set, the large sparse coefficients should be mostly concentrated on the same-class training samples and therefore yield an SCI that approaches 1. On the other hand, if the test sample is an irrelevant outlier, then its sparse coefficients should spread almost evenly across the whole training set and yield an SCI close to 0. Thus, the outlier detection criterion [2] is established, by setting a threshold \(\tau \in (0, 1)\), where a test sample is rejected as outlier if \(SCI(\alpha) < \tau\).

We verify the robustness of the proposed method over the Georgia-Tech HG and the HAuslan databases. As recommended in [2], we incorporate approximately half of all the classes into the training set but keep the test set containing samples from all the classes. Thus almost half of the test set are considered as irrelevant outliers with respect to the dictionary. For the two databases, the number of classes employed in the training set are 8 and 48 respectively. We test the performance of the proposed algorithm (CovSVDK + Kernelized SRC) by ranging \(\tau\) from 0 to 1 with 0.01

### Table 4
Multi-class classification comparison among various methods over the Auslan database. Proposed 1 is based on 10-fold cross-validation; For proposed 2, the data pool is divided into 2 folds, i.e., one fold for training and the other fold for test, according to [27].

step size. The resulting Receiver Operator Characteristic (ROC) curves (Fig. 9), indicate that: (1) the proposed CovSVDK outperforms classical LDA in outlier detection; (2) Kernelized SRC demonstrates improved robustness compared to SRC; and (3) the Area Under Curve (AUC) of the proposed framework exceeds the AUC of other listed approaches.

5. Experiments on classifying real-world univariate time series data

In this section, we evaluate the proposed classifier Kernelized SRC with nonlinear kernel function \( k(C_1) \) over 20 datasets (data1) from UCR Time-Series Repository [30]. Raw time series are directly treated as feature vectors \( \phi(C_1) \) without using CovSVDK, which is effective only when \( n \geq 2 \). The regularization parameter \( \gamma \) is set to 0.001. All columns in \( P(K + \gamma I) \) are normalized to unit \( \ell_2 \)-norm prior to sparse coding. The dictionary employed is the kernel matrix with compression rates \( f_d = N \in \{0.10, 0.25, 0.50\} \) induced by random projection, where none means no dimensionality reduction. The best result from the four cases is reported.

We compare Kernelized SRC with state-of-the-art time series classifiers, i.e., 1NN-Best Warping Window DTW [12], Time Series based on a Bag-of-Features representation (TSBF) [31], as well as 7 classic classifiers.\(^6\) The error rates of all methods are listed in Table 9, from which we can see that Kernelized SRC leads other algorithms by yielding the lowest error rate in 7 out of the

\[^6\] To avoid the similarity values out of range, a normalizing \( \phi(C_1) \) to unit \( \ell_2 \)-norm or dividing the matrix entries by \( N \) is needed. We choose the former strategy in this work.

\[^7\] The information regarding classic machine learning algorithms is summarized in http://www.cs.ucr.edu/~eamonn/time_series_data/WekaOnTimeSeries.xls.

Fig. 11. Comparison between Kernelized SRC and SRC. (a) accuracy scatter plot; (b) expected accuracy gain versus actual accuracy gain. Note that regions marked as TP/TN represent we correctly predict Kernelized SRC is better/worse than SRC; region FN means that we predict Kernelized SRC is worse than SRC but the fact is the opposite; region FP means that we predict Kernelized SRC is better than SRC but the fact is the opposite. Practically, only FP is the truly bad case [32].

Fig. A1. Discriminative properties of SVD for MTS data from the HAuslan database. (a) Pairwise comparison of singular values between two MTS data, both representing sign “Alive”; (b) pairwise comparison of singular values between two MTS data, respectively representing the signs “Alive” and “All”; (c) comparison of the directions of the singular vector pairs. Group 1 is the comparison between two MTS data from the same class “Alive” and group 2 is the comparison between two MTS data from classes “Alive” and “All” respectively.
20 datasets. In particular, we visualize the accuracy scatter plot between Kernelized SRC and 1NN-Best Warping Window DTW [12], which is considered one of the best time series classifiers. As shown in Fig. 10, the proposed classifier slightly outperforms 1NN-Best Warping Window DTW in 11 out of 20 datasets.

In addition, to fully justify the effectiveness of the proposed kernelization strategy, we test SRC over the 20 datasets and compare it with Kernelized SRC by visualizing the accuracy scatter plot. Fig. 11(a) shows that using kernel trick significantly improves the classification performance, as Kernelized SRC outperforms SRC in 19 out of 20 datasets. Moreover, a classifier is useful only if we can predict ahead of time on which datasets it will generate higher accuracy. We therefore perform further experiments to verify the reliability of Kernelized SRC by evaluating the expected accuracy gain versus the actual accuracy gain [32]. To acquire the expected accuracy gain, we conduct leave-one-out cross-validation within the training set for both algorithms. The gain is calculated as [32] \( g = \text{Accuracy Kernelized SRC} / \text{Accuracy SRC} \). As depicted in Fig. 11(b), 19 out of the 20 dots are in region TP with the remaining 1 in region TN, which indicates that the performance of Kernelized SRC is completely predictable over the 20 datasets. From the same figure, we also observe that a remarkable 20% or even higher performance increase compared to SRC is achieved via kernelization over a majority of the datasets. The impressive results validate that the proposed Kernelized SRC is very effective for time series classification.

6. Conclusion and future work

In this paper, we propose a novel sparse representation based framework for classifying complicated human gestures captured as multi-variate time series (MTS). First, we propose a feature extraction strategy, called CovSVDK, which is invariant to inconsistent lengths and temporal disorder across MTS data, robust to variability within human gestures, and efficient to compute. In addition, we propose a new approach to kernelize sparse representation by introducing a relaxation to the fitness constraint. This technique is generic and can be applied to kernelizing other sparse coding algorithms. Using this technique, we derive a classifier called Kernelized SRC, which is very effective in classifying MTS data and univariate time series as shown in the experiments.

In our future work, the proposed approach will be combined with a multi-layer structure that can model complicated temporal variations to further improve the recognition performance. The performance of incorporating nonlinear kernel function into Kernelized SRC for classifying gesture MTS data will also be extensively investigated.

Appendix A. SVD properties of MTS data

As shown in Fig. A1(a), the singular values between two same-class MTS data, both standing for the sign “Alive” from HAuslan...
meaning that their directions are similar. On the other hand, if the principle component of two same-class MTS data is close to 1, illustrated in Figs. B1 and B2. Here Australian Sign Language (Auslan) database is employed by only keeping such that each MTS contains two attributes, i.e., n = 2. Applying SVD to each MTS yields two singular vectors, each with dimension \( \lambda_1 \) and \( \lambda_2 \) extracted from 100 training MTS data corresponding to the 1st and the 2nd singular vector respectively. Two test samples (Test 1 and Test 2), all associated to class 1, are selected. For Test 1, the same-class neighbor is consistently near it in both sub-feature spaces (Fig. B1(c) and (e)). For Test 2, three same-class neighbors are consistently close to it in both sub-feature spaces (Fig. B1(d) and (f)), while the similarities between Test 2 and samples from other classes vary significantly throughout the two sub-feature spaces. Using CovSVDK features, SRC can leverage the consistent closeness between the test sample and its same-class neighbors across different sub-feature spaces by computing a universal sparse code. Thus, Test 1 and Test 2 are correctly classified into class 1, as shown in Fig. B2(e) and (f). On the other hand, the classification scheme using one single singular vector, i.e., Eq. (2), causes misclassification, as shown in Fig. B2(a)–(d).

Appendix B. Effectiveness of CovSVDK features

The robustness of the proposed CovSVDK feature extraction is illustrated in Figs. B1 and B2. Here Australian Sign Language (Auslan) database is employed by only keeping x, y information, such that each MTS contains two attributes, i.e., n = 2. Applying SVD to each MTS yields two singular vectors, each with dimension 2. Fig. B1(a) and (b) are 2D sub-features (i.e., \( \lambda_1/\|\lambda_1\|_2 \) and \( \lambda_2/\|\lambda_2\|_2 \)) extracted from 100 training MTS data corresponding to the 1st and the 2nd singular vector respectively. Two test samples (Test 1 and Test 2), all associated to class 1, are selected. For Test 1, the same-class neighbor is consistently near it in both sub-feature spaces (Fig. B1(c) and (e)). For Test 2, three same-class neighbors are consistently close to it in both sub-feature spaces (Fig. B1(d) and (f)), while the similarities between Test 2 and samples from other classes vary significantly throughout the two sub-feature spaces. Using CovSVDK features, SRC can leverage the consistent closeness between the test sample and its same-class neighbors across different sub-feature spaces by computing a universal sparse code. Thus, Test 1 and Test 2 are correctly classified into class 1, as shown in Fig. B2(e) and (f). On the other hand, the classification scheme using one single singular vector, i.e., Eq. (2), causes misclassification, as shown in Fig. B2(a)–(d).

References

Yin Zhou received the B.S. degree in electrical engineering from Beijing Jiaotong University, China in 2009. He is currently a Ph.D. student in the ECE department, University of Delaware. His research interests include machine learning, computer vision, sparse signal processing and stereo vision.

Kai Liu received the B.S. and the M.S. degrees in computer science from the Sichuan University, China in 1996 and 2001, and the Ph.D. degree in electrical engineering from the University of Kentucky, USA in 2010, respectively. He is currently a postdoctoral researcher at the Information Access Lab in the University of Delaware since September 2010. His main research interests include computer/machine vision, active/passive stereo vision, image processing and gesture recognition.

Rafael E. Carrillo (S’07) received the B.S.E.E. and the M.S.E.E. degrees (with honors) from the Javeriana University, Bogotá, Colombia, in 2003 and 2006 respectively. He was a research assistant and a visiting lecturer from 2003 to 2006 at the Javeriana University. Currently, he is a Ph.D. candidate at the Department of Electrical and Computer Engineering at the University of Delaware, Newark, DE. His research interests include signal and image processing, visual speech processing, compressive sensing, inverse problems and computer vision.

Kenneth E. Barner (S84–M92–SM00) received the B.S.E.E. degree (magna cum laude) from Lehigh University, Bethlehem, Pennsylvania, in 1987. He received the M.S.E.E. and the Ph.D. degrees from the University of Delaware, Newark, Delaware, in 1989 and 1992, respectively. For his dissertation "Permutation Filters: A Group Theoretic Class of Non-Linear Filters," Dr. Barner received the Allan P. Colburn Prize in Mathematical Sciences and Engineering for the most outstanding doctoral dissertation in the engineering and mathematical disciplines. Dr. Barner was the duPont Teaching Fellow and a Visiting Lecturer at the University of Delaware in 1991 and 1992, respectively. From 1993 to 1997 Dr. Barner was an Assistant Research Professor in the Department of Electrical and Computer Engineering at the University of Delaware and a Research Engineer at the duPont Hospital for Children. He is currently Professor and Chairman in the Department of Electrical and Computer Engineering at the University of Delaware, and a Senior Member of the IEEE. Dr. Barner is the recipient of a 1999 NSF CAREER award. He was the co-chair of the 2001 IEEE–EURASIP Nonlinear Signal and Image Processing (NSIP) Workshop and a guest editor for a special issue of the EURASIP Journal of Applied Signal Processing on Nonlinear Signal and Image Processing. Dr. Barner is a member of the Nonlinear Signal and Image Processing Board and is co-editor of the book Nonlinear Signal and Image Processing: Theory, Methods, and Applications, CRC Press, 2004. Dr. Barner was the Technical Program Co-Chair for ICASSP 2005 and is currently serving on the IEEE Signal Processing Theory and Methods (SPTM) technical committee, previously served on the IEEE Bio–Imaging and Signal Processing (BISP) technical committee, and is currently a member of the IEEE Delaware Bay Section Executive Committee. Dr. Barner has served as an associate editor of the IEEE Transactions on Signal Processing, the IEEE Transaction on Neural Systems and Rehabilitation Engineering, and the IEEE Signal Processing Magazine. Dr. Barner is currently the Editor in Chief of the Journal Advances in Human–Computer Interaction, an associate editor for IEEE Signal Processing Letters, a member of the Editorial Board of the EURASIP Journal of Applied Signal Processing, and served as a guest editor for that journal on the Super–Resolution Enhancement of Digital Video and Empirical Mode Decomposition and the Hilbert–Huang Transform special issues. His research interests include signal and image processing, robust signal processing, nonlinear systems, sensor networks and consensus systems, compressive sensing, human–computer interaction, haptic and tactile methods, and universal access. Dr. Barner is a member of Tau Beta Pi,Eta Kappa Nu, and Phi Sigma Kappa.
